1 Abstract

Current estimates of the global terrestrial carbon fluxes between the atmosphere indicate a net sink into soil carbon (not accounting for land use change emissions, Friedlingstein et al. (2023)). A key factor to the uncertainty of the terrestrial carbon sink is quantification of terrestrial soil carbon fluxes, which vary across time and ecosystem type. Robust estimation of soil carbon fluxes on a sub-daily level requires measurements of soil CO_2 concentration, water content, temperature, and other environmental measurements and soil properties. These data are publicly available from the National Ecological Observatory Network at 47 different sites spanning a range of 20 different ecoclimatic domains. We present an R software package (`neonSoilFlux`) that acquires soil environmental data and to computes soil carbon flux at a half-hourly time step at a user-specified NEON site and month in a tidy user format. By design, users with a range of proficiency in the R statistical language can access the `neonSoilFlux` R package. Soil carbon fluxes and associated uncertainties are computed using the flux gradient method via a variety of existing approaches. To validate the computed fluxes, we separately measured soil carbon fluxes with automated sensors at six focal NEON sites. The validation confirmed that a primary challenge in reducing soil carbon flux uncertainty is correctly characterizing diffusivity and soil water content across the soil profile. Outputs from the `neonSoilFlux` package contribute to existing databases of continuous soil carbon measurements, providing near real-time estimates of a critical component to the terrestrial carbon cycle.

3 Introduction

Soils contain the largest reservoir of terrestrial carbon (Jobbágy & Jackson, 2000). A critical component of this reservoir is soil organic matter, the accumulation of which is influenced by biotic factors such as above-ground plant inputs (Jackson et al., 2017). These inputs in turn are influenced by environmental factors such as growing season length, temperature, and moisture (Desai et al., 2022), which also affect the breakdown of soil organic matter and its return to the atmosphere. Across heterogeneous terrestrial landscapes, the interplay between these biotic and abiotic factors influence the size of the soil contribution to the terrestrial carbon sink (Friedlingstein et al., 2023). However, the heterogeneity of these processes across diverse ecosystems in the context of rapid environmental change leads to large uncertainty in the magnitude of this sink in the future, and thus a pressing need to quantify changes in soil carbon pools and fluxes across scales.

Ecological observation networks such as the United States' National Ecological Observatory Network (NEON) and others (e.g. FLUXNET or the Integrated Carbon Observation System) present a significant advancement in the nearly continuous observation of biogeochemical processes at the continental scale. Notably, at 47 terrestrial sites across the continental United States, NEON provides half-hourly measurements of soil CO_2 concentration, temperature, and moisture at different vertical depths. Each of these NEON sites also encompasses measurements of the cumulative sum of all ecosystem carbon fluxes in an airshed using the eddy covariance technique (Baldocchi, 2014). Soil observations provided by NEON are on the same timescale and standardized with eddy covariance measurements from FLUXNET. These types of nearly continuous observational data (NEON and FLUXNET) can be used to reconcile differences between model-derived or data-estimated components of ecosystem carbon flux (Jian et al., 2022; Luo et al., 2011; Phillips et al., 2017; J. Shao et al., 2015; P. Shao et al., 2013; Sihi et al., 2016).

Beyond direct observations of soil CO_2 concentrations and other environmental variables such as moisture or temperature, estimated or observed soil carbon fluxes are a key metric for understanding change in soil carbon pools over time (Bond-Lamberty et al., 2024). A soil carbon flux to the atmosphere (F_S, units μmol m^{-2} s^{-1}), represents the aggregate process of transfer of soil CO_2 to the atmosphere from physical and biological processes (e.g. diffusion and respiration). Measurements of soil carbon fluxes can be coupled with empirical or process models of soil carbon. Soil carbon fluxes can be assumed to encompass soil carbon respiration from autotrophic or heterotrophic sources (Davidson et al., 2006), typically assumed to be static across the soil biome and modeled with a exponential Q_{10} paradigm (Bond-Lamberty et al., 2004; Chen & Tian, 2005; Hamdi et al., 2013).

One method by which F_S is measured in the field is through the use of soil chambers in a closed, well-mixed system (Norman et al., 1997) with headspace trace gas concentrations measured with an infrared gas analyzer (IRGA). F_S can also be estimated from soil CO_2 measurements at different depths in the soil using the flux-gradient method (Maier & Schack-Kirchner, 2014). This method is an approach that uses conservation of mass to calculate flux at a vertical soil depth z at steady state by applying Fick's law of diffusion. A simplifying assumption for the flux-gradient method is that there is no mass transfer in the other spatial dimensions x and y (Maier & Schack-Kirchner, 2014). The diffusivity profile, a key component of this calculation, varies across the soil depth as a function of soil temperature, soil volumetric water content, atmospheric air pressure, and soil bulk density (Millington & Shearer, 1971; Moldrup et al., 1999; Sallam et al., 1984).

Databases such as the Soil Respiration Database (SRDB) or the Continuous Soil Respiration Database (COSORE) add to the growing network of resources for making collected observations of soil fluxes available to other workers (Bond-Lamberty, 2018; Bond-Lamberty et al., 2020; Bond-Lamberty & Thomson, 2010; Jian et al., 2021; Jiang et al., 2024). However, these databases currently encompass primarily direct soil measurements of fluxes (i.e. those using methods like the closed-chamber method described above). Currently, NEON provides all measurements to calculate F_S from Fick's law, but soil flux as a derived data product was descoped from the initial network launch due to budget constraints (Berenbaum et al., 2015). Deriving estimates of F_S using continuous sensor data across NEON sites thus represents a high priority.

This study describes an R software package, `neonSoilFlux`, that can be used to derive a standardized estimate of F_S at all terrestrial NEON sites. After calculating these flux estimates, we then validated them against direct chamber-based field observations of soil carbon dioxide flux from a subset of terrestrial NEON sites spanning six states.

Key objectives of this study are to:

1. Apply the flux-gradient method to estimate soil CO_2 flux from continuous sensor measurements across NEON sites.
2. Benchmark estimated soil carbon fluxes against field measurements (e.g. direct measurements of soil flux).
3. Identify sources of error in the flux-gradient approach across diverse sites in order to guide future work.

4 Materials and Methods

4.1 Field methods

4.1.1 Focal NEON Sites

In order to acquire field data to validate model predictions of flux, we selected six terrestrial NEON sites for analysis. We conducted field measurement campaigns at these sites, which span a range of environmental gradients and terrestrial domains (Table 1). SJER, SRER, and WREF were visited during May and June of 2022, and WOOD, KONZ, and UNDE during May and June of 2024.

Over the course of two field campaigns in 2022 and 2024, we conducted week-long visits at each site. In consultation with NEON field staff, we first selected a specific plot in the soil sampling array to maximize the concurrent availability of sensor data. We then made measurements of flux on an hourly or half-hourly interval for 8 hours each day after letting temporarily-installed soil collar(s) equilibrate for approximately 24 hours.

Table 1: Listing of NEON sites studied for field work and analysis. $\overline{T_S}$: average soil temperature during field measurements. $\overline{SWC}$: average soil water content during field measurements. Soil plot refers to the particular location in the soil sensor array (denoted as HOR by NEON) where field measurements were made.

Site (NEON site ID)	Location	Ecosystem type	Mean annual temperature	$\overline{T_S}$ (°)	Mean annual precipitation	$\overline{SWC}$ (%)	Field measurement dates	Soil plot
Santa Rita Experimental Range (SRER)	31.91068, -110.83549	Shrubland	19.3°C	47.6°	346 mm	4.0%	29 May 2024 - 01 June 2024	004
San Joaquin Experimental Range (SJER)	37.10878, -119.73228	Oak woodland	16.4°C	41.7°	540 mm	1.2%	01 June 2022 - 04 June 2022	005
Wind River Experimental Forest (WREF)	45.82049, -121.95191	Evergreen forest	9.2°C	15.3°	2225 mm	27.2%	07 June 2022 - 09 June 2022	001
Chase Lake National Wildlife Refuge (WOOD)	47.1282, -99.241334	Restored prairie grassland	4.9°C	14.9°	495 mm	14.9%	03 June 2024 - 09 June 2024	001
Konza Prairie Biological Station (KONZ)	39.100774, -96.563075	Tallgrass Prairie	12.4°C	23.4°	870 mm	23.4%	29 May 2024 - 01 June 2024	001

Table 1: Listing of NEON sites studied for field work and analysis. $\overline{T_S}$: average soil temperature during field measurements. $\overline{SWC}$: average soil water content during field measurements. Soil plot refers to the particular location in the soil sensor array (denoted as HOR by NEON) where field measurements were made.

Site (NEON site ID)	Location	Ecosystem type	Mean annual temperature	$\overline{T_S}$ (°)	Mean annual precipitation	$\overline{SWC}$ (%)	Field measurement dates	Soil plot
University of Notre Dame Environmental Research Center (UNDE)	46.23391, -89.537254	Deciduous forest	4.3°	13.0°	802 mm	13.0%	22 May 2024 - 25 May 2024	004

4.1.2 Soil collar placement

Either one (2022 sampling campaign) or two (2024 sampling campaign) PVC soil collars (FIXME: diameter) were installed in close proximity to the permanent NEON soil sensors at each site. The soil plot where measurements were taken was chosen at each site in consultation with NEON staff to maximize likelihood of quality soil sensor measurements during the duration of the IRGA measurements at each site.

IN PROGRESS: Add graphic of soil plot layout and placement of soil collar(s) – could make diagram in OmniGraffle?

4.1.3 Infrared gas analyzer measurements of soil CO_2 flux

During the summer 2022 field campaign, a LI-COR 6800 with soil flux chamber attachment was used to measure soil fluxes for 8 hours each day on an hourly interval. During the summer 2024 field campaign, the LI-6800 measurements were taken on a half-hourly interval and were paired with an automated soil flux chamber setup (FIXME multiplexer, IRGA, chamber model numbers) that made automated measurements on a half-hourly interval 24 hours a day while we were on site. Each instrument was paired with a soil temperature and moisture probe (FIXME: Stevens model #) that was used to make soil temperature and moisture measurements concurrent with the CO_2 flux measurements.

IN PROGRESS: Dead bands, measurement duration, instrument self-testing.

4.1.4 Post-collection processing of data

IN PROGRESS: LI-COR SoilFluxPro software to assess dead band and measurement duration.

4.2 `neonSoilFlux` R package

We developed an R package (`neonSoilFlux`; https://CRAN.R-project.org/package=neonSoilFlux) to compute half-hourly soil carbon fluxes and uncertainties from NEON data. The objective of the `neonSoilFlux` package is a unified workflow soil data acquisition and analysis that supplements existing data acquisition software through the `neonUtilities` R package (https://CRAN.R-project.org/package=neonUtilities). Figure 1 outlines the basic workflow of the package.

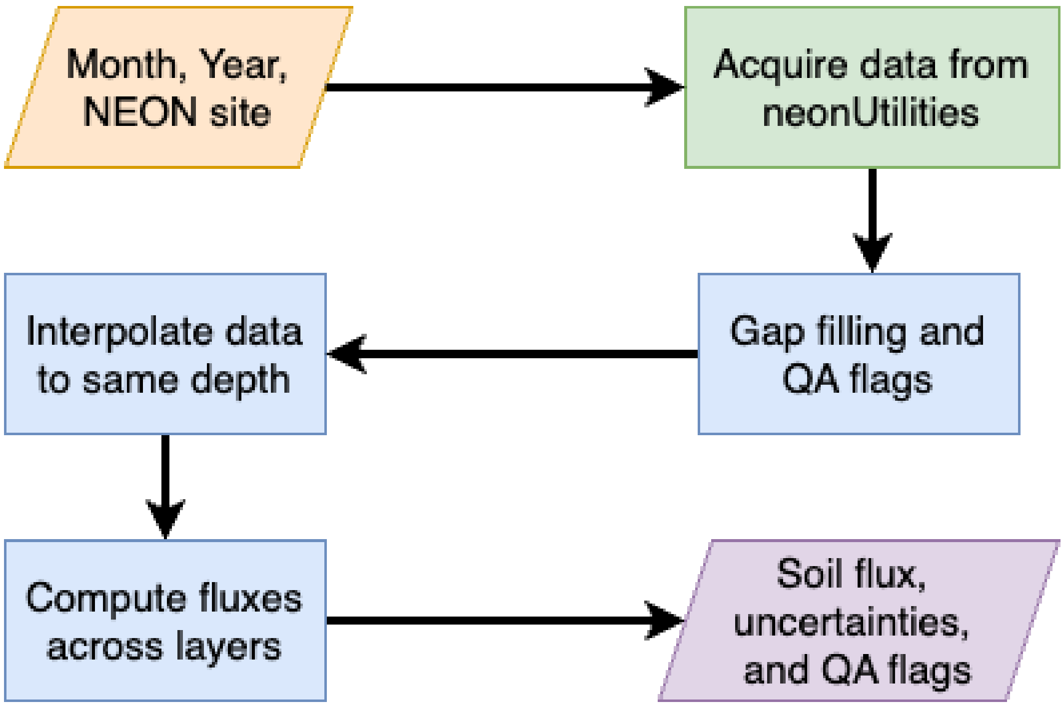

Figure 1: Diagram of `neonSoilFlux` R package. For a given month, year and NEON site (orange parallelogram), the package acquires all relevant data to compute F_S using the `neonUtilities` R package (green rectangle). Data are gap-filled according to reported QA flags and interpolated to the same measurement depth before computing the soil flux, uncertainties, and final QA flags (blue rectangles). The package reports the associated soil flux, uncertainties, and quality assurance (QA) flags for the user (purple parallelogram).

At a given NEON observation there are five different replicate soil sensor plots, each with measurements of soil CO_2 concentration, soil temperature, and soil moisture at different depths. The `neonSoilFlux` package acquires measured soil water content (National Ecological Observatory Network (NEON), 2024e), soil CO_2 concentration (National Ecological Observatory Network (NEON), 2024b), barometric pressure from the nearby tower (National Ecological Observatory Network (NEON), 2024a), soil temperature (National Ecological Observatory Network (NEON), 2024d), and soil properties (e.g. bulk density) (National Ecological Observatory Network (NEON), 2024c). The static soil properties were collected from a nearby soil pit during site characterization and are assumed to be constant at each site.

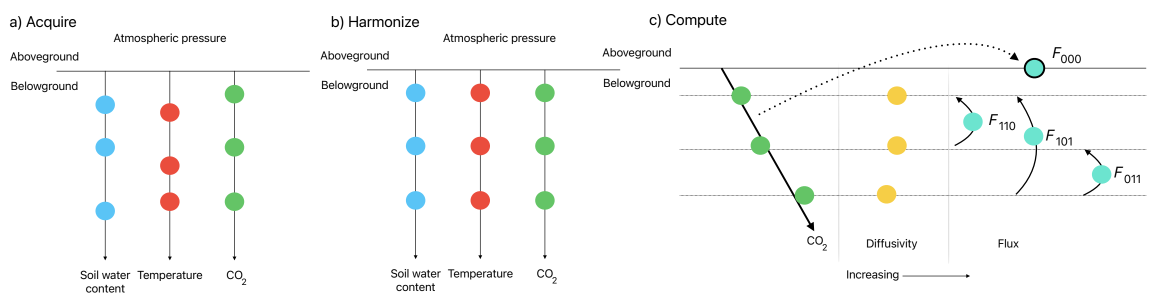

Figure 2: Model diagram for data workflow for the `neonSoilFlux` R package. a) Acquire: Data are obtained from given NEON location and horizontal sensor location, which includes soil water content, soil temperature, CO_2 concentration, and atmospheric pressure. All data are screened for quality assurance, with gap-filling of missing data reported. b) Any belowground data are then harmonized to the same depth as CO_2 concentrations using linear regression. c) The flux across a given depth is computed via Fick's law, denoted with F_{ijk}, where i, j, or k are either 0 or 1 denoting the layers the flux is computed across (i = closest to surface, k = deepest). F_{000} represents a flux estimate where the gradient dC/dz is the slope of a linear regression of CO_2 with depth.

The workflow to computing a value of F_S with the `neonSoilFlux` consists of three primary steps, illustrate in Figure 2. First, NEON data are acquired for a given site and month via the `neonUtilities` R package (yellow parallelogram and green rectangle in Figure 1 and Panel a in Figure 2). Acquired environmental data can be exported to a comma separated value file for additional analysis. Quality assurance (QA) flags with an observation are reported as an indicator variable.

The next step is harmonizing the data to compute soil fluxes across soil layers. This step consists of three different actions (blue rectangles in Figure 1 and Panel b in Figure 2). If a given observation by NEON is reported as not passing a quality assurance check, we applied a gap filling method to replace that measurement with its monthly mean at that same depth (Section 4.2.1). Belowground measurements of soil water and soil temperature are then interpolated to the same depth as soil CO_2 measurements. The diffusivity (Section 4.2.2) and soil flux across different soil layers (Section 4.2.3) are then computed.

The final step is computing a surface soil flux through extrapolation to the surface (purple parallelogram in Figure 1 and Panel c in Figure 2). Uncertainty on a soil flux measurement is computed through quadrature. An aggregate quality assurance (QA) flag for each environmental measurement is also reported, representing if any gap-filled measurements were used in the computation of a soil flux. Within the soil flux-gradient method, several different approaches can be used to derive a surface flux (Maier & Schack-Kirchner, 2014); the `neonSoilFlux` package reports four different possible values of soil surface flux (Section 4.2.3).

4.2.1 Gap-filling routine

NEON reports QA flags as a binary value for a given measurement and half-hourly time. We replaced any flagged measurements at a location's spatial depth z with a bootstrapped sample of the monthly mean for all un-flagged measurements for that month. These measurements are represented by the vector $\mathbf{m}$, standard errors σ, and the 95% confidence interval (the so-called expanded uncertainty, Farrance & Frenkel (2012)) ϵ. All of these vectors have length M. We have that $\vec{\sigma}_i \leq \vec{\epsilon}_i$. We define the bias as $\mathbf{b} = \sqrt{\epsilon^2 - \sigma^2}$.

We generate a vector of bootstrap samples of the distribution of the monthly mean $\overline{m}$ and monthly standard error $\overline{\sigma}$ the following ways:

1. Randomly sample from the uncertainty and bias independently: σ_j and the bias $\mathbf{b}_k$ (not necessarily the same sample).
2. Generate a vector $\mathbf{n}$ of length N, where $\mathbf{n}_i$ is a random sample from a normal distribution with mean m_i and standard deviation σ_j. Since $M < N$, values from $\mathbf{m}$ will be reused.
3. With these N random samples, $\overline{y}_i = \overline{\vec{x}} + \vec{b}_k$ and s_i is the sample standard deviation of $\vec{x}$. We expect that $s_i \approx \vec{\sigma}_j$.
4. The reported monthly mean and standard deviation are then computed $\overline{\overline{y}}$ and $\overline{s}$. Measurements and uncertainties that did not pass the QA check are then substituted with $\overline{\overline{y}}$ and $\overline{s}$.

This gap-filling method described here provides a consistent approach for each data stream, however we recognize that other gap-filling alternatives may be warranted for longer-term gaps (e.g. such as correlations with other NEON measurement levels and soil plots), or measurement specific gap-filling routines. We discuss the effect of gap-filling on our measurements in Section 6.

4.2.2 Soil diffusivity

Soil diffusivity D_a at a given measurement depth is the product of the diffusivity in free air $D_{a,0}$ (m^2 s^{-1}) and the tortuosity ξ (no units) (Millington & Shearer, 1971).

We compute $D_{a,0}$ with Equation 1:

$$D_{a,0} = 0.0000147 \cdot \left(\frac{T_i + 273.15}{293.15} \right)^{1.75} \cdot \left(\frac{P}{101.3} \right) \quad (1)$$

where T_i is soil temperature (°C) at depth i (National Ecological Observatory Network (NEON), 2024d) and P surface barometric pressure (kPa) (National Ecological Observatory Network (NEON), 2024a).

Previous studies by Sallam et al. (1984) and Tang et al. (2003) demonstrated the sensitivity of modeled F_S depending on the tortuousity model used to compute diffusivity. At low soil water content, the choice of tortusoity model may lead to order of magnitude differences in D_a, which in turn affect modeled F_S. The `neonSoilFlux` package uses two different models for ξ. representing the extremes reported in Sallam et al. (1984). The first approach uses the Millington-Quirk model for diffusivity, Equation 2 (Millington & Shearer, 1971):

$$\xi = \frac{(\phi - SWC_i)^{10/3}}{\phi^2} \tag{2}$$

In Equation 2, SWC is the soil water content at depth i (National Ecological Observatory Network (NEON), 2024e) and ϕ is the porosity (Equation 3), which in turn is a function of soil physical properties (National Ecological Observatory Network (NEON), 2024c):

$$\phi = \left(1 - \frac{\rho_s}{\rho_m}\right)(1 - f_V) \tag{3}$$

In Equation 3, ρ_m is the particle density of mineral soil (2.65 g cm^{-3}), ρ_s the soil bulk density (g cm^{-3}) excluding coarse fragments greater than 2 mm (National Ecological Observatory Network (NEON), 2024c). The term f_V is a site-specific value that accounts for the proportion of soil fragments between 2-20 mm. Soil fragments greater than 20 mm were not estimated due to limitations in the amount of soil that can be analyzed (National Ecological Observatory Network (NEON), 2024c). We assume there are no pores within rocks.

The second approach to calculate ξ is the Marshall model (Marshall, 1959), where $\xi = \phi^{1.5}$, with ϕ defined from Equation 3.

4.2.3 Soil flux computation

We applied Fick's law (Equation 4) to compute the soil flux F_{ij} (μmol m^{-2} s^{-1}) across two soil depths i and j:

$$F_{ij} = -D_a \frac{dC}{dz} \tag{4}$$

where D_a is the diffusivity (m^2 s^{-1}) and $\frac{dC}{dz}$ is the gradient of CO_2 molar concentration (μmol m^{-3}, so the gradient has units of μmol m^{-3} m^{-1}). The soil surface flux is theoretically defined by applying Equation 4 to measurements collected at the soil surface and directly below the surface. Measurements of soil temperature, soil water content, and soil CO_2 molar concentration across the soil profile allow for application of Equation 4 across different soil depths. Each site had three measurement layers, so we denote the flux between which two layers as a three-digit subscript F_{ijk} with indicator variables i, j, and k indicate if a given layer was used (written in order of increasing depth), according to the following:

- F_{000} is a surface flux estimate using the intercept of the linear regression of D_a with depth and the slope from the linear regression of CO_2 with depth (which represents $\dfrac{dC}{dz}$ in Fick's Law). Tang et al. (2003) used this approach to compute fluxes in an oak-grass savannah.
- F_{110}, F_{011} are fluxes across the two most shallow layers and two deepest layers respectively. The diffusivity used in Fick's Law is always at the deeper measurement layer.

When used as a surface flux estimate we assume CO_2 remains constant above this flux depth.

- F_{101} is a surface flux estimate using linear extrapolation using concentration measurements between the shallowest and deepest measurement layer. Hirano et al. (2003) and Tang et al. (2005) used an approach similar to F_{101} in a temperate deciduous broadleaf forest and ponderosa pine forest respectively.

Uncertainty in all F_{ijk} is computed through quadrature (Taylor, 2022).

4.3 Post processing evaluation

Following collection of field measurements from the LICOR and calculation of the soil fluxes from `neonSoilFlux` package, we compared measured F_S (from the LICOR instruments) to a given soil flux calculation `neonSoilFlux` for each site and flux computation method. Statistics included the associated R^2 value, root mean squared error (RMSE), and signal to noise ratio (SNR), defined as the ratio of a modeled soil flux (F_{ijk}) from `neonSoilFlux` to its quadrature uncertainty (σ_{ijk}).

We observed that the range of values (e.g. $F_{ijk} \pm \sigma_{ijk}$ was much larger than the measured field flux. We evaluated $|F_S - F_{ijk}| < (1-\epsilon)\sigma_{ijk}$, where F_S is a measured field soil flux from the LICOR 6800 (the LICOR 8250 was used at only three sites). The parameter ϵ was an uncertainty reduction factor to evaluate how much the quadrature uncertainty could be reduced while maintaining precision between modeled F_{ijk} and measured F_S.

Finally, for a half-hourly interval we also computed a *post hoc* D_a using the LICOR flux along with the CO_2 surface gradient reported by NEON using the measurement levels closest to the surface.

5 Results

Figure 3 reports the timeseries of out the measured fluxes from the LICOR 6800 and 8250 compared to modeled soil fluxes from the `neonSoilFlux` R package. Figure 4 and and computed fluxes and uncertainty at each measurement site. Results are reported in local time. Positive values of the flux indicate that there is a flux moving towards the surface. For ease of clarity the fluxes at F_{111} and F_{000} are only shown in the top row (surface), followed by the fluxes at individual separate layer (F_{100}, F_{010}, F_{001}). Overall, with the exception of WREF and SRER (discussed later) the computed fluxes were on the same order of magnitude and timing as the measured field fluxes.

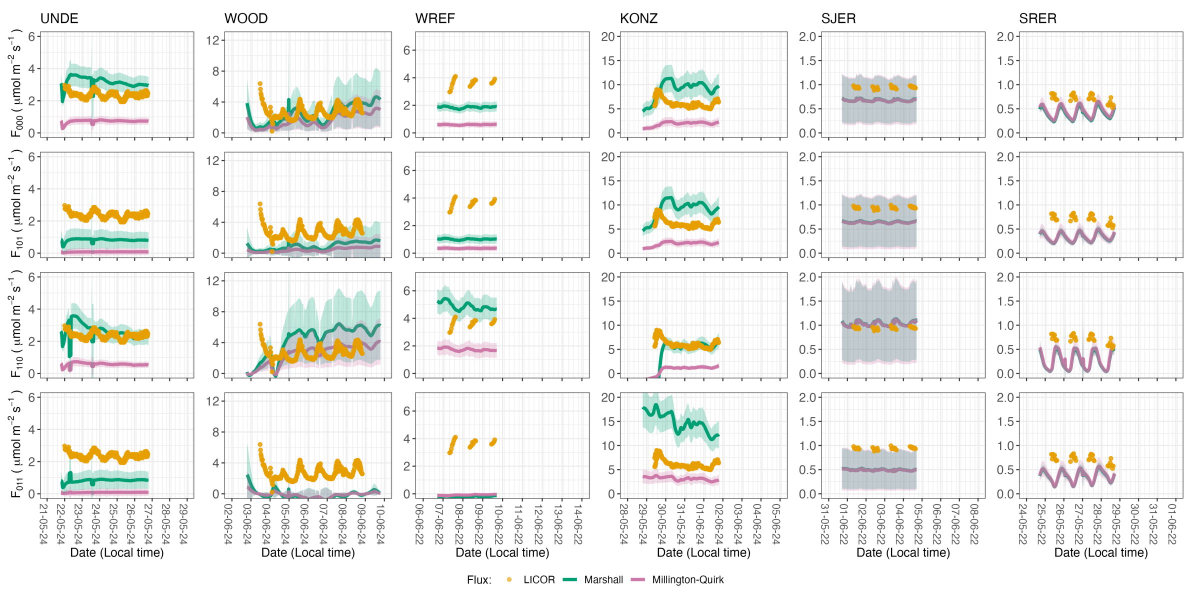

Figure 3: Timeseries of both measured F_S (yellow circles) and modeled soil fluxes (green or purple lines) by the `neonSoilFlux` R package. Fluxes from the `neonSoilFlux` R package are separated by the diffusivity model used (Millington-Quirk or Marshall, Section 4.2.2). Vertical axis labels in the first column represent the measurement levels where the flux-gradient approach is applied (Section 4.2.3). Ribbons for modeled soil fluxes represent $\pm$ 1 standard deviation. Results are reported in local time.

For a given half-hourly time period, the `neonSoilFlux` packages assigns a QA flag for a mea-

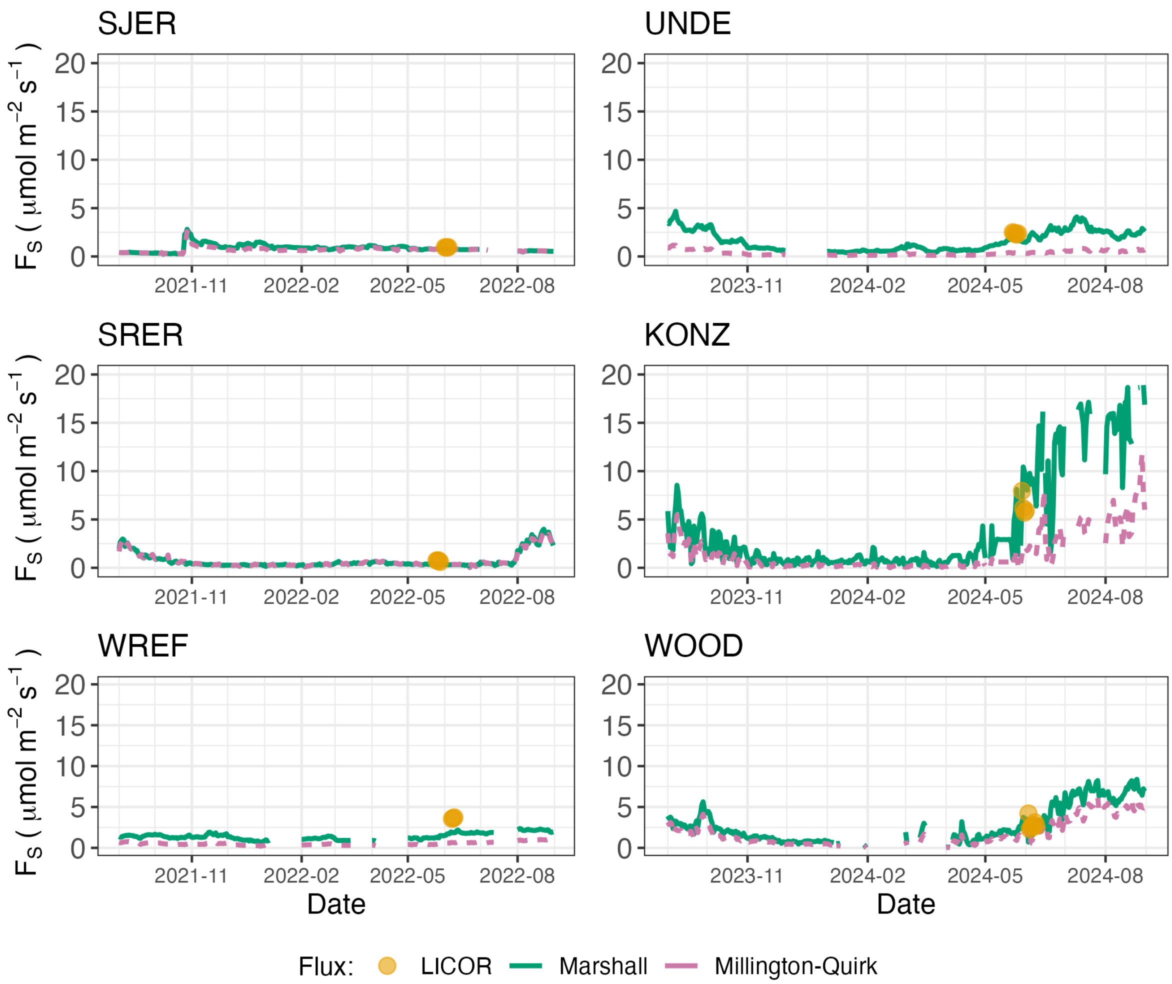

Figure 4: Timeseries of both daily-averaged field F_S (yellow circles) and daily ensemble averaged soil fluxes (green or purple lines) by the `neonSoilFlux` R package, separated by the diffusivity model used (Millington-Quirk or Marshall, Section 4.2.2). The timeseries of modeled fluxes are a daily ensemble average of all flux-gradient approaches (F_{000}, F_{101}, F_{011}, F_{110}, Section 4.2.3).

surement if more one values across all measurement depths uses gap-filled data (Section 4.2.1). Panel a of Figure 6 reports the distribution for all input environmental measurements at each site when field measurements were made. Soil fluxes are computed from 4 different types of input measurements (T_S, SWC, P, and CO_2), any of which could have a QA flag in a half-hourly interval. Panel b of Figure 6 displays at each site the distribution of the number of different gap-filled measurements used to compute a half-hourly flux. The largest contribution to gap-filled measurements was soil water. SJER and WOOD utilized the largest number of gap-filled measurements, which were primarily SWC and T_S.

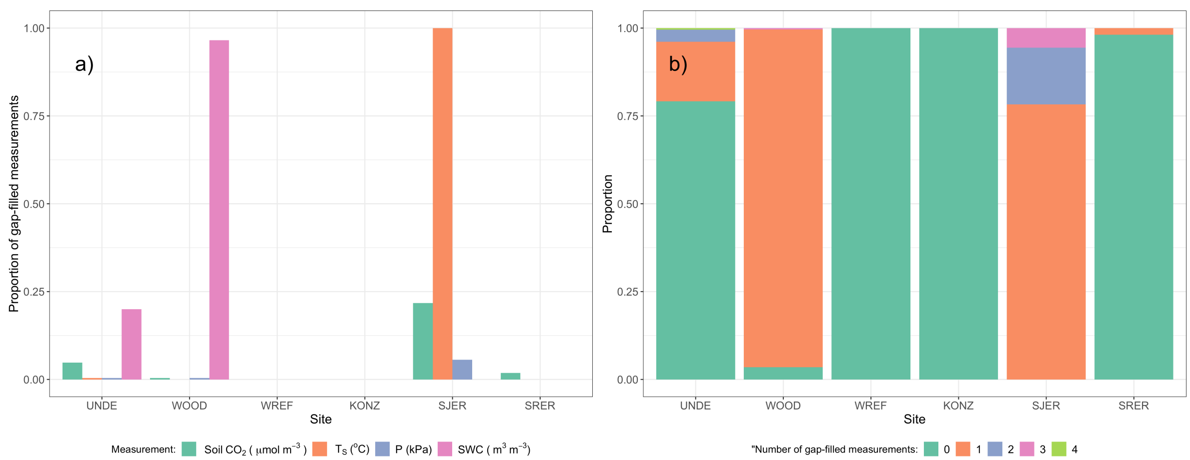

Figure 6: Panel a) Proportion of input gap-filled environmental measurements used to generate F_S from the `neonSoilFlux` package, by study site. Panel b) distribution of the usage of gap-filled measurements at each site.

Figure 7 reports both the computed SNR and the proportion of measured field fluxes within the modeled uncertainty for a given flux computation method F_{ijk} (Section 4.3). Here, values of SNR greater than unity indicates a reported uncertainty is smaller, propogated by quadrature from a relatively higher precision from measured input variables (CO_2, T_S, SWC, or P). The sensitivity to the uncertainty reduction factor (ϵ, bottom panels in Figure 7) demonstrates how accuracy could be improved if modeled uncertainty σ_{ijk} decreases.

Figure 8 reports the distribution of D_a (from both the Marshall and Millington-Quirk methods,

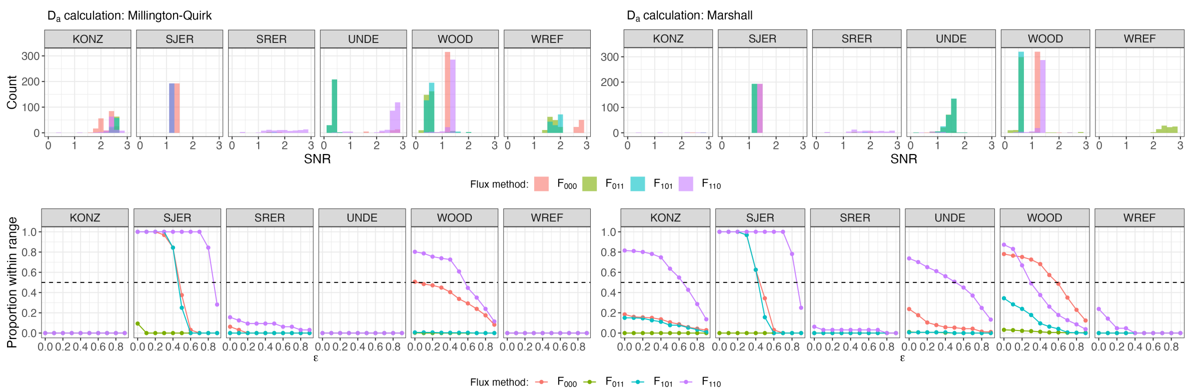

Figure 7: Top panels: distribution of SNR values across each of the different sites for modeled effluxes from the `neonSoilFlux` package, depending on the diffusivity calculation used (Millington-Quirk or Marshall, Section 4.2.2). Bottom panels: Proportion of measured F_S within the modeled range of a flux computation method F_{ijk} given an uncertainty reduction factor ϵ, or $|F_S - F_{ijk}| < (1-\epsilon)\sigma_{ijk}$.

Section 4.2.2) at each study site, and the *post hoc* computation of D_a (Section 4.2.2).

6 Discussion

This study presents a unified data science workflow to efficiently process automated measurements of belowground soil CO_2 concentrations, water, and temperature to infer estimates of soil surface CO_2 effluxes through application of Fick's Law (Equation 4). Our core goals in this study were: (1) to generate estimates of soil flux from continuous soil sensor data at terrestrial

NEON sites using the flux-gradient method and then (2) to compare those estimates to field-measured fluxes based on the closed chamber approach at six NEON focal sites. We discuss our progress toward these core goals through (1) an overall evaluation of the flux-gradient approach (and uncertainty calculation) and (2) site-specific evaluation of differences in estimated vs measured fluxes.

6.1 General evaluation of flux-gradient approach

Key assumptions of the flux-gradient approach are that CO_2 concentrations increase throughout the soil profile. We found that this condition was met at XXX% across the study period. Periods where this gradient condition are not met generally are connected to biophysical processes such soil wetting events (e.g. KONZ), which have the effect of temporarily reducing the soil respiration or efflux. When modeling soil respiration, typically a non-linear response function is considered, that also considers soil type as well (Bouma & Bryla, 2000; Yan et al., 2016, 2018). For the `neonSoilFlux` package soil type is connected to the bulk density, which was separately determined at a site.

The largest source of uncertainty to improve reliability of the flux estimate is to prevent the usage of gap-filled data. Three sites (KONZ, SRER, and KONZ) had more than 75% of half-hourly periods with no-gap filled measurements. Two sites (SJER and WOOD) had more than 75% of half-hourly intervals with just one gap-filled measurement. While WREF reported no gap-filled measurements, field data collection occurred following a once-in-a century rainstorm with soils observed at their water holding capacity. We recommend that whenever available, local field knowledge is supplementary to any QA filtering protocol of fluxes from the `neonSoilFlux` package.

We recognize that this gap-filling approach may lead to gap-filled values that are quite different from the actual values, such as an underestimate of soil moisture following rain events. Further extensions of the gap filling method could use more sophisticated gap-filling routines, similar to what is used for net ecosystem carbon exchange (Falge et al., 2001; Liu et al., 2023; Mariethoz et al., 2015; Moffat et al., 2007; Zhang et al., 2023). The current gap-filling routine provides a consistent approach that can be applied to each data stream, but further work may explore alternative gap-filling approaches.

Based on this approach, we would *a priori* expect $F_{011} \leq F_{101} \leq\leq F_{110} \leq F_{000}$ because the previous flux estimates ones correspond to deeper depths which will could miss CO_2 produced in shallower layers. Additionally, field flux measurements should correlate with F_{000} because they represent surface fluxes.

6.2 Evaluation of flux-gradient approach at each site

Derived results from the `neonSoilFlux` package have patterns that are consistent, and comparable, to those directly measured to the field (Figure XXX). The advantage to the `neonSoilFlux` package is the calculation of fluxes across different measurement depths, allowing for additional site-specific customization. Here application of the flux-gradient method provides a baseline estimate of soil fluxes that could be complemented through additional field measurements (e.g. LICOR).

The six sites studied provide separate case studies for considerations when applying the flux-gradient method to evaluate resulting uncertainties and fluxes For example, SRER is characterized by sandy soil, which also led to the highest observed field soil temperatures. At SRER the flux across the top two layers (F_{110}) produced a pattern of soil flux consistent with the observed field data. The remaining methods F_{101}, F_{011}, or F_{000} are derived from information at the deeper layer, which is decoupled both in terms of temperature and CO_2 concentration.

In addition, KONZ is a site that experienced a significant rain event prior to sampling with eventual drying out over the course of the experiment. In this case we observed storage of soil water which increased the soil CO_2 at the top layer, leading to negative values of flux at the start of the experiment, with the fluxes drying out afterwards. In this case only when the soil dried out (or returned to a baseline level), that the fluxes at the provided layer would work out in this case.

When considering systematic deployment of this method across a measurement network, we faced a number of independent challenges for consideration.

Figure 7 illustrates the tradeoff between accuracy for modeled fluxes (defined here as closeness to field-measured F_S) and precision defined by the SNR, and how this is confounded by the choice of diffusivity model used. MORE HERE

Diffusivity discussion

In developing and validating our approach, we faced a number of challenges related to data availability, including… gap filling, sensor calibration, depth interpolation, rainstorms, etc These errors are all

6.3 Recommendations for future method development

The `neonSoilFlux` package provides three different approaches of values for a soil flux. We believe these approaches reflect a variety of site-specific determination and assumptions used to generate a soil flux measurement (Maier & Schack-Kirchner, 2014), with the choice of method having a determinative approach on reported values. Reported results could further be distilled down using ensemble averaging averaging approaches (Elshall et al., 2018; Raftery et al., 2005).

Figures XXX suggests that the provided uncertainty from `neonSoilFlux` is an overestimate compared to what is actually computed. When $\epsilon = 0$ in Figure Figure 7, that means we are just using the reported uncertainty from neonSoilFlux. Looking at that (epsilon = 0) shows field measurements UNDE, KONZ, SJER are 100% within the reported intervals from neonSoilFlux. But those sites tend to have a SNR < 1, so the uncertainty is pretty noisy. For UNDE, we could even reduce the uncertainty by a factor of 75% (epsilon = 0.75), more than half of the field measurements will still be within the reported intervals. For KONZ, we are still within 70% of the reported intervals when uncertainty is reduced by 90%. That suggests that while the reported accuracy (as compared to field measurements), we do have higher precision.

These challenges notwithstanding, the method used here and made available in the `neonSoilFlux` R package has the potential to produce nearly continuous estimates of flux across all terrestrial NEON sites. These estimates are a significant improvement on available approaches to constrain the portion of ecosystem respiration attributable to the soil. This, in turn, aids in our ability to understand the components of net ecosystem flux assessed at these sites using the co-located eddy flux towers.

- Refine estimates to provide a realistic constraint on surface concentration measurements, thereby increasing the gradient.
- Apply machine learning algorithms (e.g. random trees) or model averaging techniques to generate a single flux estimate across each sites spatial location
- Benchmarking flux results to estimates provided by Net ecosystem carbon exchange.

7 Conclusions

We have here presented an R package `neonSoilFlux` for the estimation of soil CO_2 fluxes from continuous buried soil sensor measurements across terrestrial National Ecological Observatory Network sites. We compared the predicted fluxes to those measured directly using a field-based closed chamber approach. We find that…
